• VIRUS ON WEBSITE

Any website can be infected by viruses. Where does the virus on the website, what it can do and how to fight it?

Virus gets to the website by changing the code of one or more pages. Access to change the code, it gets in most cases using the password to access the website files (FTP), which is stored in the respective programs. The virus does not change the look and feel of a website, but only adds to the website malicious code that exploit vulnerabilities in the browser to infect your visitors.

Visitor's computer becomes infected with a so-called virus-loader (downloader), which, after successful infection load instructions and the necessary files (including other viruses) from server "host" of the virus. The consequences of infection can be very different - from stealing passwords and personal data before turning the computer into "zombies" - part of a large network of infected computers, which often send out spam or engaged disabling other websites. Such networks are called botnets (from the English. Botnet: "bot" - short for "robot" "Net" - "Network"). Some botnets containing hundreds of thousands of infected computers around the world.

Even if not store passwords on the drive and in FTP-client, there's always several ways to leak. For example, Trojans, keyloggers, which read password from the keyboard as you type. Another way - it sniffers, listen to your local area network for password transmission (because FTP passwords are not encrypted, and transmitted in the clear.) Enough to have their local network one infected computer and access to the website on FTP can be made public. In addition, the FTP-password leakage may occur due to the fault (including the unconscious) of third parties who have received the password for the work on the website and similar actions.

Very often to access the files of crackers use "hole" in the popular content management systems (CMS), for example, Joomla! or Wordpress. This is not because they are very popular, but mainly often because the components of them developed by amateurs without taking into account the requirements of security.

When you protect your computer from viruses, there are many anti-virus programs, to protect the website of this diversity there. The fact that the website has been hacked and a virus is introduced, the owner of resources usually only after the virus online discovered an anti-virus program and is listed in the "black list" of the infected websites, to bring the website from which the very difficult.

No less difficult to determine in what specific modules of the website has malicious code, given that these modules can be several hundred. Determine the change of a date for their change does not always work, as the malicious code can be copied and so change that date. Similarly, in the introduction of new modules
